Chapter 7

Geriatric Care

Otolaryngology
Obstructive sleep apnea-hypopnea syndrome (OSAHS) is a prevalent disorder characterized by intermittent cessation of airflow during sleep that results in excessive daytime sleepiness. Common presenting symptoms include habitual snoring, witnessed apneas, nighttime gasping or arousals, daytime sleepiness or fatigue, unrefreshing sleep, and morning headaches. The diagnosis of OSAHS is established if the patient has both an apnea-hypnea index (AHI) score ≥ 5 on overnight monitoring, and evidence of excessive daytime sleepiness or fatigue. OSAHS is a prevalent disorder in Western society estimated to affect up to 5 percent of the adult male and 3 percent of the adult female population. It is estimated that the rate of AHI ≥ 5 is 50-60 percent in older men and 30-40 percent in older women, which is three times greater than the general adult population. Menopausal status appears to be a major determinant of the rate of OSAHS in women. In the large population-based Wisconsin Sleep Cohort Study, postmenopausal women were found to be 3.5 times more likely than premenopausal women to have AHI scores ≥ 15. A number of theories have been proposed to explain the increased prevalence of OSAHS in older age groups, including ongoing loss of neuromuscular tone, decreased hormone levels, and changes in the ratio of fat to lean body mass.

Although the prevalence of OSHAS appears to increase steadily with age, the overall prevalence of the disorder appears to level off after the age of 65 years. The reason for the plateau after age 65 is not clear but may be explained in several ways: (1) the incidence of new cases of OSAHS decreases after age 65; (2) the mortality rate of OSAHS cases increases after age 65; or (3) OSAHS remits at older age. Because there is little evidence to support death caused directly by OSAHS or spontaneous remission of OSAHS, a reduction in incidence after age 65 is the currently favored explanation; however, further investigation is needed to clarify this issue.
Sleep Patterns in Older Adults

Changes in sleep duration and architecture occur as a normal part of the aging process. The duration and need for sleep appears to lessen with age. The average 70-year-old sleeps only 6 hours per night but may make up for loss of nocturnal sleep with daytime naps of 1 to 2 hours. In addition, many older adults have increased difficulty falling to sleep once in bed (increased sleep latency), and have greater difficulty staying asleep (decreased sleep efficiency). The number of co-morbid medical conditions that have an impact on sleep increases with age and includes depression, arthritis, gastroesophageal reflux, prostate hypertrophy, and renal and pulmonary disorders. In addition, older adults are more likely to take medications such as diuretics that cause nocturia. As a result, up to 40 percent of older individuals complain of sleep disturbance and undesired daytime fatigue.

The challenge for the physician presented with complaints of sleep disturbance in older individuals is to determine the degree to which symptoms are related to normal age-related changes in sleep pattern versus an underlying medical disorder or a primary sleep disorder. A thorough review of the patient’s past medical history, medications, and alcohol and stimulant (caffeine, nicotine) use is required. Improving the management of co-morbid conditions (for example, reflux, arthritic pain, or prostate hypertrophy) will often result in sleep improvement. A thorough sleep history (table 1) helps identify patients at risk of the primary sleep disorders seen most commonly in older adults: OSAHS, restless leg syndrome, insomnia, and sleep maintenance insomnia. It is important to note that sleep maintenance insomnia, which is characterized by early morning awakenings, is highly associated with either alcohol abuse or depression in older individuals. Patients suspected of a primary sleep disorder should undergo a full-night polysomnography in order to establish the presence and severity of a sleep disorder. The diagnosis of OSAHS can be established in patients with daytime sleepiness or fatigue who are found to have an AHI ≥ 5 on overnight polysomnography.

Clinical Sequelae of OSAHS

Untreated OSAHS has been associated with reduced quality of life as well as a number of serious health conditions. Reduced quality of life. Daytime sleepiness caused by OSAHS often results in decreased energy, loss of concentration,
poor job performance, and reduced social interaction. In addition, the loud snoring that often accompanies OSAHS may result in poor sleep for the sufferer’s bed partner. An AHI ≥ 5 has been associated with concentration difficulty but not memory tasks on self-assessment exams. OSAS patients demonstrate significant improvement in daytime sleepiness, and in numerous quality-of-life parameters including physical functioning, social functioning, vitality, and general health perception after treatment. The relationship between sleepiness and level of AHI is not well defined, especially in older populations, with many people with AHI ≥ 5 reporting minimal or no daytime sleepiness on self-reported examination.

Cardiovascular morbidity and mortality. Evidence supports an increase in cardiovascular mortality five years after diagnosis in untreated patients with severe OSAHS patients compared with treated patients. Another study found that men under age 60 with snoring and excessive daytime sleepiness were twice as likely to die over a 10-year study period compared with subjects without snoring or snoring without sleepiness. Two large prospective studies suggest that untreated, loud, habitual snorers have a 30-40 percent greater risk of myocardial infarction or stroke relative to nonsnorers. In contrast, a study by Jennum et al., which contained greater numbers of older individuals (age 54-74 years), failed to demonstrate a significant association between untreated snoring and cardiovascular morbidity or mortality. Therefore, it has been hypothesized that the relationship between OSAHS and cardiovascular morbidity and mortality may be stronger in younger OSAHS patients compared with older patients.

Hypertension. It has been hypothesized that systemic arterial hypertension is the cause of the increased cardiovascular morbidity and mortality observed in patients with sleep-disordered breathing. Laboratory evidence has demonstrated that sustained arterial hypertension can be induced in animal models subjected to intermittent airway occlusion during sleep. The current epidemiological evidence shows a strong and consistent association between OSAHS and hypertension. Four large population-based cross-sectional studies found that the odds of hypertension were 1.4 to 2.5 times greater in patients with an AHI ≥ 5 compared with controls. A prospective analysis of the Wisconsin Sleep Cohort study found that even minimal elevation in AHI scores was associated with a 42 percent increased risk of developing hypertension over a four-year period. Currently it is unclear the degree to which blood pressure can be lowered by treatment of OSAHS with CPAP or other methods.

Motor vehicle accidents. Epidemiological and laboratory evidence both suggest that patients with OSAHS are at greater risk for motor vehicle accidents (MVA). Patients with an AHI ≥ 15 were 7.3 times more likely to have had multiple MVAs in the five years before their study, compared with those with lower or no apnea. Hospitalized MVA victims were found to be 6.3 times more likely to have an AHI ≥ 5 than community controls.
In addition, patients with severe OSAHS performed significantly worse on a driving simulator than controls without OSAHS.  

All patients ≥ 65 years should be screened by history and physical examination for sleep-disordered breathing given the extensive prevalence of at least mild apnea (AHI ≤ 15) in this age group and the severe potential health and quality-of-life consequences of undiagnosed sleep apnea. The evidence supports treatment of OSAHS in individuals with the following findings:

• AHI ≥ 5 with excessive daytime sleepiness
• AHI ≥ 5 with cardiovascular co-morbidities
• AHI ≥ 15 with or without excessive daytime sleepiness

Patients with an AHI between 5 and 15 who do not have excessive daytime sleepiness are likely to be at low risk for cardiovascular sequelae and unlikely to be compliant with therapy, because they have no self-perceived sleepiness. Treatment selection depends largely on the level of sleep apnea, presence of medical co-morbidities, presence of anatomical deformities, and patient preference.

1. Common primary sleep disorders in older adults include all of the following EXCEPT:
   a. Obstructive sleep apnea-hypopnea syndrome
   b. Cataplexy
   c. Insomnia
   d. Sleep maintenance insomnia
   e. Restless leg syndrome

2. Changes in sleep pattern with age include which of the following:
   a. Increased sleep requirement
   b. Improved sleep efficiency
   c. Fewer nocturnal arousals
   d. Higher rates of insomnia
   e. Less need for napping

3. Which of the following statements is supported by current evidence:
   a. OSAHS is a major cause of systemic hypertension.
   b. OSAHS is a major cause of memory loss in older individuals.
   c. Treatment of OSAHS significantly improves self-perceived quality of life.
   d. The association between cardiovascular mortality and OSAHS is stronger in older individuals.
   e. The treatment of OSAHS significantly lowers systemic high blood pressures.
