Abstract
Epistaxis is a common complaint in the general population and treatment of epistaxis is a common procedure in emergency departments. In the COVID-19 era, procedures involving airway management are particularly at risk for healthcare workers, due to the high virulence of virus, also through aerosol, and the risk of contagion from asymptomatic patients. In this paper, we propose a simple memorandum of clinical recommendations to minimize the operator infection risk deriving from epistaxis management. The correct use of personal protective equipment and the strict compliance of the behavioral guidelines are essential to reduce the potential risk of infection. In particular, the use of filtering masks is strictly recommended since all patients, including those referring for epistaxis, should be managed as COVID-19 positive in the emergency department. The safety of health-care workers is essential not only to safeguard continuous patient care but also to limit virus transmission.

Keywords: epistaxis, COVID-19, emergency, otolaryngology.

Introduction
The outbreak of Sars-Covid-2 2019 (COVID-19) has evolved rapidly into a public health crisis and has spread exponentially to other parts of the world. Medical professionals caring for COVID-19 patients are at high risk of contracting the infection, since the high virulence and the occurrence of contagion from asymptomatic individuals; in Italy, the percentage of healthcare workers infected by COVID-19 accounts for about 10% of total patients. Procedures involving airway management are particularly at risk for potential generation of aerosols or droplet laden with viral particles, thus specific guidelines have been proposed for some aerosol-generating procedures in hospitalized patients such as tracheostomy.
Among diseases requiring ED prompt treatment, epistaxis accounts for about 0.5% of all ED visits and up to one-third of all otolaryngology-ED procedures \[^7\]. In this article, we propose a simple memorandum of clinical and behavior recommendations to minimize the infection risk for healthcare workers involved in the treatment of epistaxis in the ED.

### Clinical Recommendations for epistaxis

#### Personal protection

As a general rule, all patients should be managed as COVID-19 positive with highest level of PPE by healthcare workers. The use of disposable equipment must be strictly recommended. The use of filtering masks has been widely debated and have demonstrate to protect against aerosols. FFP3 (Europe) or N99 (US) masks, that allow a minimum 99% filtration, must be preferred to any other option \[^8\]. However, in case of FFP3 mask absence, FFP2 or N95 masks can be used, covered by a surgical mask \[^6\]. Cap and shoe covers are considered necessary for safely dressing, eye protection through the use of surgical goggles or a face shield is required, and the use of double gown is preferable, where available. The use of double nitrile gloves is recommended \[^3\] \[^6\].

#### Clinical assessment

Before clinical procedure, all patients should be asked about contact at risk for COVID-19, fever, respiratory symptoms. Patient referring sudden loss of smell and/or taste should be considered at high risk for COVID infection \[^9\]. Patients should wear a surgical mask covering mouth, if permitted by the clinical condition.

Prompt assessment of the severity of epistaxis should be performed by a physician or a nurse in the ED to distinguish patients that requires a prompt management from patient that do not. Patients with prolonged bleeding, bleeding from both sides of the nose or from the mouth, or any signs of acute hypovolemia (tachycardia, syncope, orthostatic hypotension) must be immediately treated, while patients with a minor active bleeding should be addressed in a non-ED setting where available.
Non-invasive intervention for nosebleed, including bi-digital compression to the lower third of the nose, should be strictly recommended before attempting more invasive interventions.

**Room setting**

Invasive treatment should be ideally performed the operating room (OR); however, well-demarcated areas within the ED complex should be used if conventional OR is not available.

Only experienced clinical team with proper PPE should be involved in treatment of simple anterior epistaxis, preferably including a surgeon and a scrub nurse. Additional clinical staff should be reserved for selected cases, anesthetist should be needed in the cases of more advantaged disease or for patients requiring sedation in a conventional OR.

**Treatment**

Nasal packing or cautery should be performed in case of failure of non-invasive procedures, like compression, or in case of a nosebleed judged to be life-threatening or unlikely to respond to further compression alone. The use of resorbable packing is recommended, if available, in order to reduce the need for future visits, although experience and local availability of resorbable packing may dictate the specific type of material used.

Posterior epistaxis requiring sphenopalatine artery ligation should be postponed until COVID-19 testing is performed. The use of local anesthetic atomized sprays should be avoided and soaked pledgets should be preferred.

Suction system should be used during the procedure within a closed system with a viral filter.

**Post-procedure recommendations**

Post-procedural instructions regarding packing removal or antibiotic prophylaxis should be provided to the patient to reduce risks of recurrences and optimizing outcomes.
“Gowning and de-gowning” procedures should be carefully executed, as improper removal may result in operator contamination (5). The post-procedure waste disposal and decontamination of equipment need careful consideration to minimize contamination of the environment. Personnel who handle the decontamination of surgical equipment should also be appropriately protected in standard PPE (Table 1).

Discussion
Epistaxis is a common compliant in the general population, and its management should be considered a COVID-19 at-risk procedure for several reasons. Firstly, the surgical treatment of epistaxis is inevitably at risk for droplets emission and viral transmission due to the close contiguity of physician and patient. Moreover, nasal packing without anesthesia or sedation may be painful, thus the patient is unable to control involuntary reflex, as coughing. Secondly, treatment of epistaxis needs a prompt medical intervention, thus presence of respiratory symptoms or contacts at risk of the patient may not be properly investigated. Thirdly, anterior nasal packing is generally performed by non-specialist physicians in various settings, including the outpatient office or emergency department. Last, “undressing/doffing” procedures after epistaxis management may be considered at risk of COVID infection for accidental contact with the contaminated PPE.

Conclusion
Treatment of epistaxis is a frequent procedure performed in the ED and exposes healthcare workers at risk of contagion. Specific recommendations should be followed before, during and after epistaxis intervention to ensure the safety of healthcare workers.
